MEXICO 1970: OCCUPATIONAL STRATIFICATION, INCOME AND REGION.
AN ANALYSIS OF CENSUS DATA

76-12-2603

Introduction

In the programme of tabulations connected with the Occupational Stratification and Social Mobility Project, the case of Mexico is uncommon: it is, in fact, the only country for which we have been able to use the variables of income and region.

Information on income was available also in other six censuses: those of Panamá, Costa Rica, Venezuela, Brazil, Colombia and Perú. But, on one side, the census data of Venezuela, Brazil and Colombia have not yet been tabulated because their samples have not been as yet made available to us; and, on the other, the information on income of the censuses of Costa Rica, Panamá and Perú was not reliable or incomplete. For instance, in the case of Costa Rica the information on income was supplied only for salaried workers. In conclusion, Mexico has the only census for which the information on income is available and worth taking advantage of. There is no need to add that this information - in spite of the limitations it presents and to which we will refer in the next section - is very valuable.

As to region, the comments need be different. Most censuses adopt a subnational division (region, department, etc.) as the basic unit of analysis, and most publish this information or supply it in census tapes. The Occupational Stratification and Social Mobility Project, however, had, so far, taken the decision of not tabulating region with the other basic variables. The reasons for this decision are two: first, the regional division is not equally significant in all countries, due to the nature of administrative partitions. I will refer later to this matter. Second, the number of tabulations and the number of cells that would be created tabulating region with the other variables is often (depending on the number of categories of the variables and the total number of cases) unmanageable or meaningless, since the number of cases per cell is too small to allow interpolation from the sample to the population.

/The case

900007859 - BIBLIOTECA CEPAL

The case of Mexico is somewhat special, due to the relatively large number of cases in the sample at our disposal. The second problem therefore, could be mitigated, if not altogether avoided. As to the first problem, no solution is possible, but as I will state later, neither is the problem so big.

This paper is an introduction to the tabulations of Mexico 1970. I will, therefore, evaluate the degree of reliability of the data, and attempt, on my own, a simple analysis of the relation between size of the middle class at the regional level, and regional development. Also, I will construct a new stratification structure, employing the income information.

Characteristics of the data

Anticipating what could be the conclusion rather than the introduction to this section, we could state that the data are weak, but this is all we have! Rather than waiting for better data, let us make sense of the available ones. To beware, however, when necessary, let us talk a little on their reliability.

As to the income information, there are two problems, the first of which is peculiar to Mexico, and the second, common to all income data:

- a) The census schedule of Mexico census asked: "cuáles fueron los ingresos aproximados de esta persona en 1969?" with three options: 'en una semana normal', 'en un mes normal', 'en un año'. In spite of the 'normal' adjective, it is legitimate to suspect that respondents answered either the most recent or the best week or month. In the presence of high rates of unemployment and underemployment, this means that extrapolation from information on week or month to that of year, or viceversa, is unwarranted; or, at least, that the reliability of the information is dubious.
- b) The reliability of income statements varies according to the income and the occupation of the respondent. Of course, this is not a peculiar trait of the Mexican census, but is no less a source of error. Specifically, on one side are understated due to the omission of income in kind. In fact, the

fact, the question in the census makes clear that computed income is pre-tax, pre-social security payments and exclusively monetary. At the other extreme of the income scale, underreporting is due to the rich men's dislike toward revealing the extent of their wealth, or otherwise to their ignorance on the true amount. All data on income therefore, should need to be corrected in order to account for these distortions.

Parenthetically, it may be stated that various works have been devoted to this task: Ifigenia de Navarrete's,^{1/} ECLA's and many others. The first author adjusts the unreliable data in the following way: first, she compares the data on disposable income reported by national accounts, and by censuses and housing surveys, finding that the datum in the latter sources (censuses and surveys) is smaller, due to the cited problem of underreporting. Second, in order to assign this difference to income brackets, she assumes that in no case families dissave (because families at poverty level have no or little savings). Thus, she attributes families which report an income lower than expenditures a level of income equal to the level of expenditures. Third, the remaining superavit is attributed to families, which spend less than they earn in proportion to the bracket's income average. Similar adjustments have been made, on the base of other assumptions to be sure, to the 1967 housing survey, (unpublished work of the Statistical Division of ECLA) but not to the 1970 census.(Table A).

This summary of the efforts made in order to improve the reliability of income distribution data helps draws the attention of the reader to the existence of the problem and cautions him. While, however, such adjustments are indispensable for research whose main or only scope is the analysis of income distribution, they become less important where others are the goals of the investigation. The possibility of correcting distortions with the help of the suggestions that emerge from the quoted works has been evaluated; but, given the nature of the investigation, which does not

focus exclusively on income distribution but on stratification, it has been discarded. We will therefore take income data as they are supplied in the census; the inferences that we draw from them however, must be taken with caution.

As to the regional information, which, with that of income, constitutes the novelty of the Mexican tabulations, two observations are in order: first, there is no doubt that its reliability is good. But second, this is not the major problem with the regional information. Rather, what is discussed is its validity.

The argument against the utility of this information is based on the internal heterogeneity of administrative regions. Since the properties of the internal composition of a region are not registered by the aggregate data, and in such properties lie part of the interest of the unit for sociological analysis, what we can know of a region from the available data is useless.

This argument, seems to me too sweeping. First, it could be applied with better reason to national units; heterogeneity is greater at this level than at the regional one. Now, sociological analysis of aggregate data, usually done applying statistical techniques is a valuable approach, if not for its capacity of providing insights, certainly for its testing potentiality. Similarly, regional analysis. Although it would be better to employ units homogeneous as to the variables we want to manipulate, nonetheless, the analysis is worthwhile if the units are heterogeneous among themselves. This is obviously the case of regions. Furthermore, we only need to recall that homogeneity can be approached combining different regions, and that, in spite of the difficulties mentioned above, recent researches have taken regions as units of analysis.^{2/} I do not think that regional units are recommendable for all purposes, but neither do I agree with those who think regional analysis is entirely useless.

Stratification and income

On various occasions I have said that we have no proof that the indicators employed to construct our stratification structure are valid. Their validity was based on common sense and the past experience. Now we can check this intuition, by verifying covariation of our status definition and income. To do so, we cross-tabulate stratum with income.

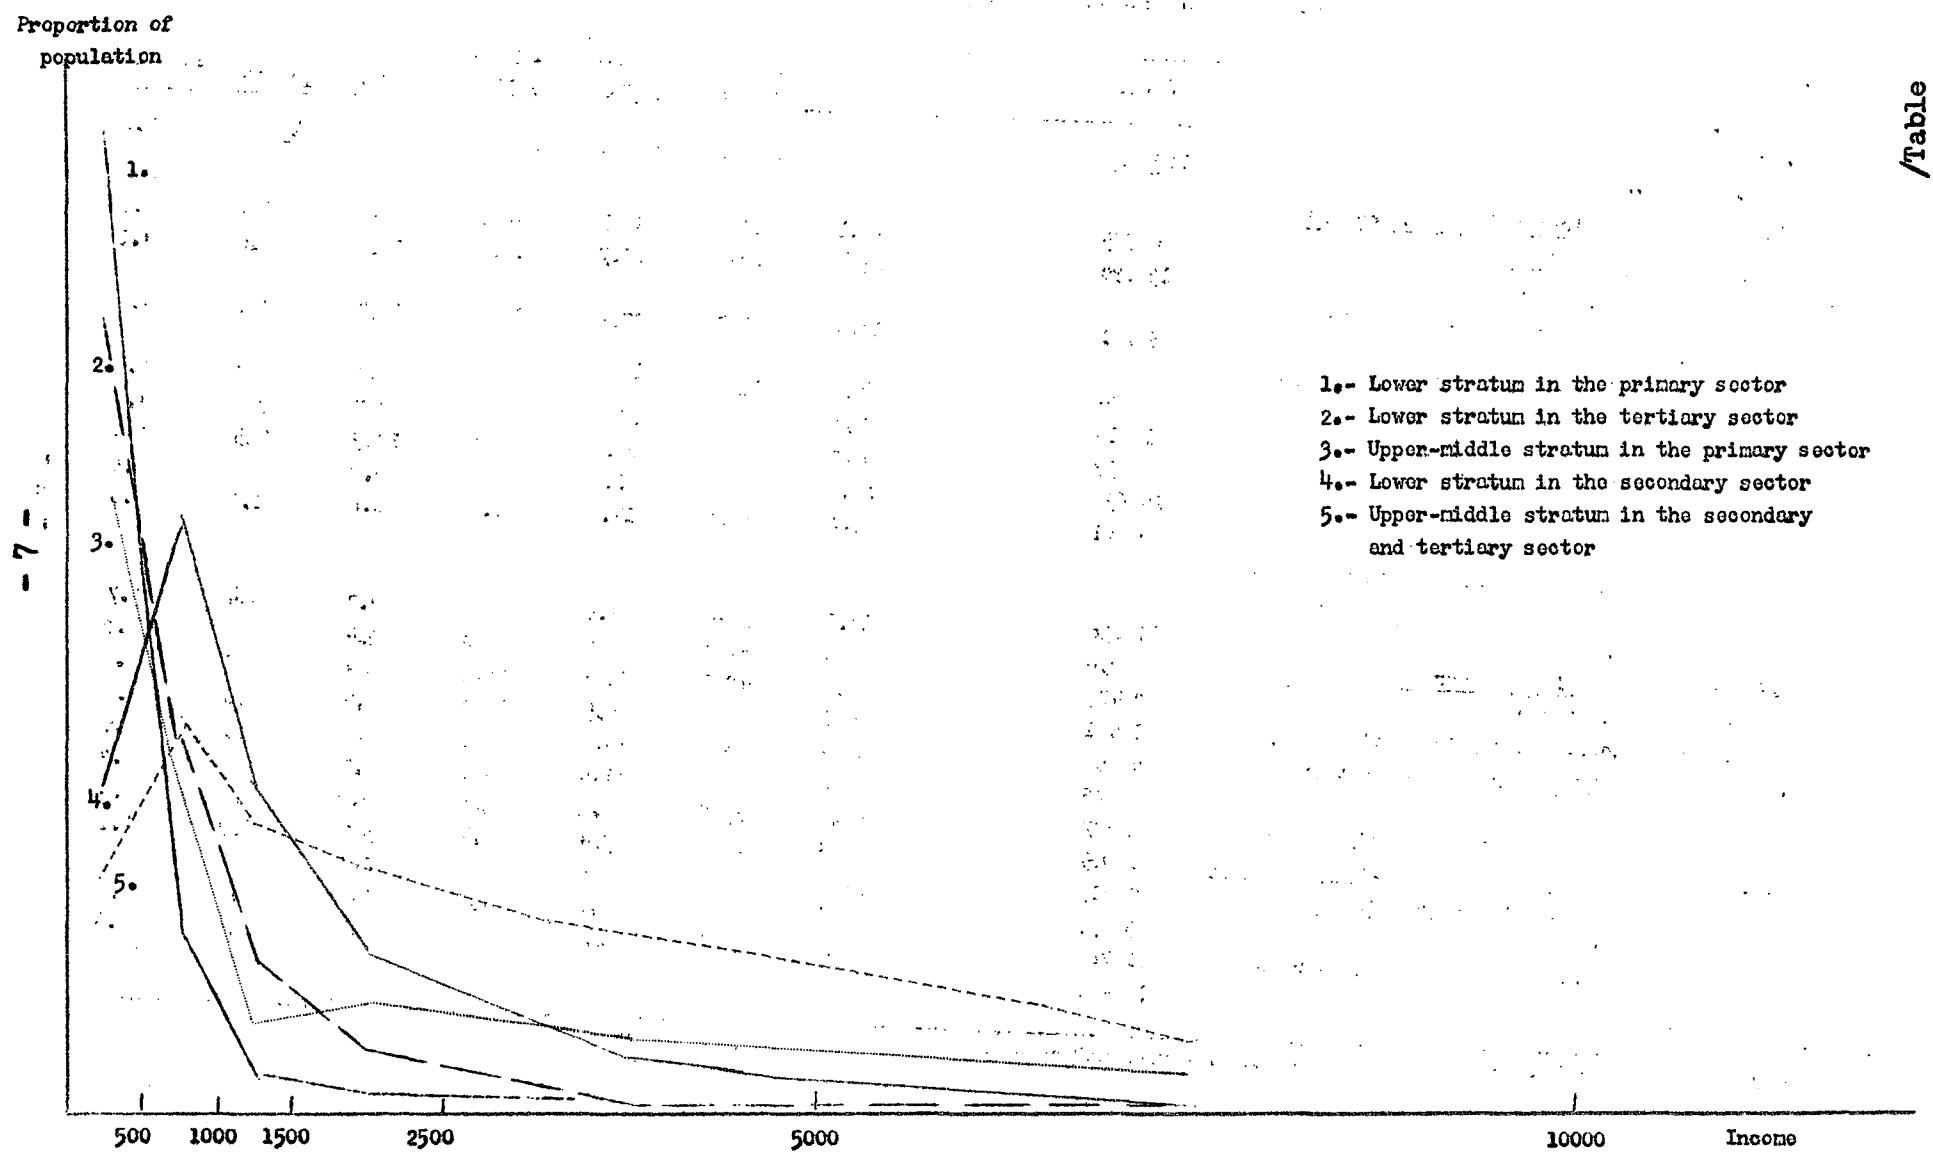

A glance at table B indicates two things:

- (a) that, as any theory of stratification leads us to expect, there is a strong covariance between stratum (defined by the cross-tabulation of occupation with occupational category) and income. If we in fact skip over inter-class differences (which we will attend below), and focus only on the five major classes (middle class in secondary and tertiary; middle class in the primary; lower class in primary; in secondary; and in tertiary) we can notice that their access to income is very different: for instance the percentage of lower class members in the < 500 income brackets is far higher than that of middle stratum members. Only 15.4% of the middle stratum against 22.3% of the lower secondary and 65.6% of the lower primary earn a monthly salary below 500 pesos. The graphic of distribution of population by income bracket for each stratum (Graphic 1) indicates in fact that strata are good discriminants with respect to income. Everything is expected. If we look, however, detainedly at the graphic, we may notice two peculiarities: that the profile of the upper-middle stratum in the primary sector is different from that of the upper-middle in secondary and tertiary; and, in turn, that this latter is similar to that of the lower stratum in the secondary. In fact, the maximum frequency for the first stratum is in the 0-500 pesos income interval, like the lower strata in the tertiary and primary; while, for the upper-middle stratum in secondary and tertiary, and lower in secondary, the maximum frequency falls in the 500-1000 income bracket. This suggests that, for low values of income, the criteria employed for the indication of status are not discriminant enough. Furthermore, in the case of the lower secondary, that their income share with respect to all other lower strata and,

/ even to

even to the upper-middle in the primary sector, is relatively good. This suggests that a good discriminant of income may be the modernity level of the sector, if we assume as is usually done, that industry is more 'modern' than agriculture. Now, I have tabulated industry with income bracket in order to verify the hypothesis (Table 5, Appendix 1). The results support the hypothesis. The "traditional" industries (agriculture, textiles, wood, non-metallic minerals) show a higher proportion of workers in the lower income categories than 'modern' ones (paper, chemicals, metallic and mechanic electrical and gas energy). Somewhat exceptional is construction, which is a 'traditional industry', but has an income institution similar to that of 'modern industries'. Let us summarize the table as follows:

Table C
PEA BY INDUSTRY AND SOME INCOME BRACKETS

	0-200	5,000 and more
1. Agriculture	33.3	.9
2. Food	7.0	4.2
3. Textile	8.9	1.5
4. Wood	21.0	2.1
5. Paper	2.3	5.8
6. Chemical	2.5	8.4
7. Non-metallic minerals	8.8	2.3

17. Social services	3.9	5.4
18. Personal services	16.8	3.3

Source: CEPAL-UNICEF tabulations: See Table 5, Appendix 1.

/It is

It is interesting to notice that industries differ as to their heterogeneity not only among but also within themselves. Some have their income concentrated around the middle, others at the extremes, suggesting, therefore, that very different realities are included in the same category. For example food production, which has a high proportion of its income in the lowest and highest categories.

Returning, however, to the upper-middle structure in the primary sector, besides the maximum in the 0-500 pesos income interval, we can notice a second maximum in the 1,500-2,500 pesos income interval. No other class shows the same profile. Therefore, it is possible to argue that this stratum is in fact constituted of two substrata, with very different constitution: the first is composed - we can imagine - of employers of few seasonal farmers, in conditions of relative poverty, whose income situation is no different from that of salaried labour or independent farmers. The second of rich owners of capitalistic enterprises.

This suggestion is not founded on any other supporting information. If one example of similar phenomenon may help, although from a very different situation, we may cite the case of the south of Italy, where the largest employers were the poorest farmers, usually women left back by their husbands working abroad. They had to hire labour for the harvest time because their family (or their own strength) was not enough even on their small farm.

We will notice later that also on other grounds, the behaviour of the upper-middle class in the primary sector is different from its 'counterpart' in the secondary and tertiary sector and similar to the lower class.

(b) that relevant differences exist also within each class. Two of these differences are particularly noticeable: first, the situation of the 'actividades por cuenta propia en el comercio'. Their percentage frequency in the lowest income bracket, is, in fact, substantially higher than the corresponding percentage of the industrial working class: 30.1 against 19.0; and very close to the 35.7 of 'cuenta propia en actividades secundarias'.

/This leads

This leads us to think that this category belongs to a greater extent to the lower than to the middle class. Again, the responsibility for this error lies in the lack of precision of the criteria employed in the construction of the stratification structure.

The second category which diverges from the mean of its stratum more than expected is that of the 'profesionales y semiprofesionales libres', that is 'técnicos, profesionales y afines que trabajan por cuenta propia'. It is difficult to explain why, since supposedly they should be the physicians, lawyers, consultants whose salaries, guessing from the fees they ask, should be high. The result may be therefore, a massive tax evasion manouver.

(c) the third observation that is worth making is that there is a consistent difference in income between salaried and independent workers, obviously, within each class. For instance, independent technicians and professionals earn less than employed professionals; independent industrial workers less than salaried workers, and so on.

Is this common to all countries? We can try to answer this question. Though data from other countries are not entirely comparable, if we consider the distribution of family heads by major income source and by quartile (that is, how many family chiefs that have, say, salary as their major income source, belong to the lowest income quartile of the whole sample) for four cases (urban Colombia, urban Paraguay, Perú and urban Venezuela) gathered in a study of Figueroa and Weisskoff,^{2/} we obtain the following Table D.

In Colombia, 56.7% of the salaried employees earn less than the median income, against 43.6% of the independent workers, and 37% of the employers. The relation between salaried employees and independent workers is opposite in Perú and in Venezuela; in the latter 47% of the first category are below the median income, against 56.8 of the independent

/workers. Two

workers. Two possible explanations could be either that, since the surveys have different coverage, the data are not comparable, or that countries have in reality different industrial structures and labour markets. As to this point, we do not know whether the employees are substantially state employees, or industrial workers belonging to the private sector, we cannot go further in specifying which employers and which industrial structures are mostly responsible for the better conditions of employees in some countries than in others. The better position of industrial workers has different causes than the same situation of public employees, although the end results of the distribution by income source presented above is the same regardless of the sector of employment. For instance, the relative position of salaried and independent workers in Venezuela may be due to the high salaries paid public employees; in Perú, it may be due to the existence of modern industrial enterprises which de facto exercise monopsony on the highly paid labour market. This is, however, only a guess.

In conclusion, the mexican data at times contradict and, at times, support the ideas produced and defended in the Occupational Stratification and Social Mobility Project: income varies with status in the five large classes, but looking at subclasses, it is possible to notice important differences. Such differences are in part due to salary differentials among industries.

A new stratification structure

On various occasions the publications of the Occupational Stratification and Social Mobility Project, criticized the methodology employed - for lack of a better one - in the construction of stratification structures. In my earlier works I stated that the criteria employed to indicate status and to define criteria of inclusion were not to a desirable degree valid (it is impossible to give confidence limits), because status is a composite concept, and should be therefore indicated by a number of criteria.

/How many

How many criteria? According to the traditionally adopted trichotomic nature of status, there should be three indicators, of class, prestige and power. The state of the art in sociology, however, is such that it would be too ambitious to try to construct indicators for all of them. Moreover, in the concrete situation of the research we are conducting - especially given the limitation of the data at our disposal - not many paths are open, and it would be useless to defend a strategy that cannot be applied.

It is worthy of note, however, that the existence of information of income besides that on occupation and occupational category allows us to construct a stratification structure more respectful of the different dimensions of status. Income refers exclusively to the type (quantity and quality) of consumption, and therefore to class, in Weber's conceptual framework. For occupation and occupational category, on the contrary the reference to consumption is strong enough but not exclusive. Occupations can indicate status on a prestige rank. In the history of stratification literature there have been in fact various attempts to rank occupations on the scale of prestige. To be sure this analysis was done especially in the United States, though examples of it can be found also in Brazil and Argentina, within the five cities project. Two things were found in these researches: that values on the prestige of occupation are shared vastly by a society, that people have the same and constantly the same idea as to the prestige of occupations. And, second, that, to a great extent, this scale is shared also by members of different cultures within the industrialized societies.

In most of these scales, one can observe three implicit evaluations:

1. Non-manual work is better than manual work.
2. Independent work is better than dependent one.
3. Less commonly, that non-agricultural work is better than agricultural one.

To transform these value judgements into a comprehensive stratification structure, however, is a complex operation. At best, if we dichotomize each scale (manual-non-manual; independent-dependent; agricultural-non-agricultural) we obtain eight combinations. This gives rise to

/two problems:

two problems: first, since this structure must then be cross-tabulated with income (on a four or five categories scale), the number of combinations we obtain is unmanageable. Second, the ranking of the eight classes obtained is not clear: do the non-manual independent agricultural have more prestige than the non-manual dependent non-agricultural? That is, which of the correlations between status and the three prestige scales has the highest slope? And, is there any interaction between them? For instance, agricultural-ness may be less important than independence, but the combination agricultural-independent may have higher scores on the prestige scale than expected.

When we reach this point, however, it becomes obvious that to pursue the investigation further in this direction we run the risk of falling into nonsense. The three evaluations of relative prestige stated above must be taken into account, but with a degree of flexibility. Instead of constructing the formal structure first and fill it then with the available data, let us cross-tabulate income and stratum at the beginning, and then, taking into account the limitations in number and reliability of the categories, decide what class structure best respects the complexity of social arrangements. The cross-tabulation of income and stratum appears in table B. 3/

In the stratification structure adopted in the occupational stratification and social mobility project five large strata, and a number of substrata had been defined: lower in primary, in the secondary, and in the tertiary sectors; upper middle in the secondary and tertiary; upper middle in the primary sector. There is no need to recall that this classification, in turn, was the result of the cross-tabulation of occupation with occupational category. Now, in order to take advantage of the income information in the construction of a new stratification structure, we must assign on each of these strata an income interval to each of the classes 4/

-
- 3/ This table is the same as Table 1, Appendix 1, obtained however, distributing the "unknown" to the other categories in proportion to each category's frequency.
 - 4/ For clarity's sake let us call the category obtained tabulating occupation and occupational category "strata", and that obtained tabulating "stratum" with income "class".

/we are

we are going to identify. For instance, if we plan to construct a trichotomic class structure (lower, middle, upper) we may decide to attribute the 1,500-5,000 pesos income interval on the "empleadores en comercio y servicios" to the middle class; it derives that the income limits for the lower and upper class are 0-1,500 and 5,000 and more respectively. Now, in order to account for the prestige dimension of status, the income intervals for the three classes must be different according to the stratum (or substratum) the intervals are drawn on. It becomes therefore possible to take into account as much as possible the three statements made above; the lower and upper income limits of the middle class will in fact vary with inverse direction with respect to prestige. Thus, the lower income limit of the middle class will be higher for manuals than for non-manuals, for agricultural than for non-agricultural occupations, and for independent than for dependent ones.

This is, at least, the goal of this new structure. Since, however, the number of income brackets at our disposal (7) is relatively small to permit many combinations, and, since, the tradeoff between income and prestige must not be too large (it would be wrong to attribute to "agricultores asalariados" a lower income limit more than twice as large as that for "gerentes", for instance), not all necessary combinations have been possible. It must be stressed, however, that this operation is arbitrary: why do we set 1,000 pesos as the divisory line between the lower and the middle class on the middle stratum? Why 1,500 on the "lower in the secondary"? It could be answered that, since 500 pesos is the average minimum salary in Mexico, the middle class must, at least, earn twice as much as this. But why not, then, 1,500? In the end, the researcher must rely on common sense, and do the best with the available data, aware, however, that changes in the criteria of classification affect substantially the resulting class distribution. (See Appendix 2.)

The following is the conversion table from the stratification structure adopted in the Occupational Stratification and Social Mobility Project and the one I am suggesting here. (Table E).

The deriving stratification structure, divided by sex is the following (Table F). This table deserves a few comments:

/Table E

1. The new stratification structure differs rather fundamentally from the earlier one as to the size of the classes. First the former did not include the upper class while this does. Even so, the upper-middle class is smaller than the corresponding classes in the new structure.

It seems to me that the new picture is more accurate than the old one. If we in fact recall that for the middle class, the lower income limit were 1,000, and 1,500 pesos, and that 500 pesos is the average minimum salary in Mexico, (see Appendix 3), it is natural to expect that the middle class member earns at least twice as much as the minimum salary, which is the 1,000 pesos (80 US\$) constituting the lower limit of the middle class for non-manual occupations.

2. The sector distribution I have adopted in the new stratification structure also differs from the usual trichotomy of primary, secondary and tertiary in that it adds to this a new category, of white collar workers. There should be a better term than this, but it did not occur to me. This category includes the members of the upper middle stratum in the secondary and tertiary of the old stratification structure. As is known, this structure was not the result of cross-tabulation of occupation, occupational category and sector as it might have seemed but, simply, of the first two properties. Sectorial apportionment was imputed from occupations: "empleadores de comercio, industria y servicios, personal de dirección en las mismas ramas, profesionales libres y dependientes" were obviously attributed to the secondary and tertiary; jointly as if they were constituting one sector, because the occupation does not distinguish them and it is very unlikely (though not impossible) that independent or dependent professionals would work in the primary sector. Remarkably, occupations of the lower strata had a clear sectorial placement: "agricultores; artesanos en hilandería y ocupaciones afines; trabajadores manuales y jornaleros; empleados en ocupaciones domésticas; trabajadores de servicios y similares". There derived an asymmetry: upper classes could not be placed into sector (excepting upper class in primary) while lower classes were easily placed. When we cross-tabulated stratum with income, the upper-middle stratum in secondary and tertiary activity must, therefore, be left aside, in a special class, which I have called "white collars".

/3. Another

3. Another distinctive improvement respect to the old stratification structure appears in the sex-class distribution. In the stratum structure, more women than men - in proportion - belonged to the upper-middle class. This, I have stated, was due to the differences in the occupational and - especially - sectorial distribution of men and women, and to the distortions produced by the only moderate reliability of occupation as indicator of status, especially in the economic aspect of this. Women are more than proportionately occupied in services and men in agriculture. Services are placed in the middle stratum more than agriculture, even at parity of status. In other words, agriculture-ness causes status to be underrated, and service-ness to be overrated. This explains why in the stratum structure, a far higher proportion of women than men belongs to the upper-middle class.

When, however, we introduce a new criterion of status, as is income, we can correct for this distortion. The validity of this correction is evident in table F the sex distribution of class: there, the class distributions of men and women though not identical are very similar, as 33.2% of all occupied males versus 32.2% females belong to the lower class. The sectorial composition of this sex stratification structure remains different as before: women continue being represented especially in the services, and men in agriculture.

Interestingly, men belong to the upper class in greater proportion than women. I do not know, however, if the small difference may give ground to theoretical speculation.

Stratification and Education

Education is sometimes added to income, prestige and power as a basic status indicators. Whether this position is justified is of no importance here. However, there is no denying that education, income and prestige covary. This clearly appears in table 3 (A & E in Appendix 1). If we look exclusively at the tabulation of education and stratum, we notice that the educational level varies with status. Only 9% of the upper-middle stratum in secondary and tertiary shows no year of education, against 25% of

/the lower

the lower stratum employed in the tertiary sector, and 42 of the agricultural workers. Furthermore, if we look at the tabulation of income and education (for each occupational stratum, thus in reality controlling for status) we must notice the convariation of the two variables as well: 34.3% of the upper-middle class in secondary and tertiary with no year of education has an income below 500 pesos; only 2.8% of the same class belongs to this income bracket for 13 and more years of education. This comparison could not be clearer. It would be interesting to know which of the three variables employed to construct the stratification structure (occupation, occupational category and education) correlates stronger with income. But this would require a statistical analysis whose difficulty is not comparable to the importance of the results. Even if we were able, in fact, to prove that education has a higher correlation with income than occupation, we could not conclude that increasing the general educational level of the population would also increase the diffusion of the distribution of income. This is a well known criticism to statistical analyses and need not be repeated here.

One phenomenon which must be stressed here is the following: already in the brief commentary to the income by stratum table, I had noticed that the profile of income distribution for the upper middle stratum in agriculture is more similar to that of the lower class in the tertiary and primary than to the upper-middle stratum in the secondary and tertiary. This phenomenon appears with greater evidence in the cross-tabulation of income with stratum and education. In fact, while the percentage of upper-middle stratum in secondary and tertiary earning less than 500 pesos is, as I said 34.30, the same percentages for the lower class in tertiary and upper-middle in primary are 66.4 and 57.3 respectively. If we look at the same percentages (for 500 pesos or less) for different levels of education, we get to the same conclusions: that the upper-middle stratum in primary has features closer to the lower stratum in the tertiary and primary than to the rest of the upper-middle stratum; or, at least, that the lower rungs of this stratum (the less educated) have the same profile as the lower strata.

/Region and

Region and stratification

At the beginning of this monograph, I have pointed to the limited validity of the category of region in population censuses.

In spite of these difficulties, however, variations existing among regions - though, not those existing within regions - can be usefully analyzed. The questions that could be asked are all those that can be asked about a nation, with some advantages and disadvantages: power structures, for instance, have been analyzed at this level more often than they have been at the national level. There are also questions specific to a regional unit: internal migrations, urbanization, industrial settlement, etc.

The issue of stratification also can be analyzed at the regional level. What I plan to do here is to give a preliminary analysis of this data with respect to one specific issue: the relation between regional development and size of the middle class. There is already a work in this direction: Torcuato Di Tella's ^{5/} on the "first impact" of economic development. There, in brief, he states that the relation between the size of the middle class and the level of economic development is curvilinear. For values of development inferior to an unspecified limit, the relation is negative, thus supporting the marxist hypothesis on the proletarization of the middle class in correspondance to the process of capitalist accumulation. For values higher than this limit, on the contrary, due to the increase in the importance of the state, to the bureaucratization of enterprises, to the pressure from below of lower classes, the middle class increases nomothetically with level of development.

The hypothesis is very interesting, and Di Tella has been one of the very few sociologists who have tried to support their ideas with reliable data.

5/ Torcuato Di Tella, "El primer impacto del crecimiento económico", Buenos Aires, Cuadernos del Instituto de Sociología, 1966.

/It was

It was noted, however, that the research design was not the most appropriate for the purpose at hand: especially, due to the fact that its unit of analysis was the region and not the national state. Given, in fact the lack of internal barriers to geographical mobility, it must be expected that the regions which experience greater development also draw greater migration. Now the effects of this migration on the size of the middle class, either contrast or complement those of the economic development, depending on the class composition of migration, whether, that is, more middle-class members or lower class members migrate out of their region. Let us imagine the process: first, a region develops relatively, increasing, therefore, its demand for labour. If more middle class members move to this region than lower class members, we would expect the size of the middle class to increase regardless of the effects of economic development. In fact, the rise in the middle class we may notice across time may be due entirely to migration.

A similar argument, with opposite propositions, of course, could be made when we observe a decrease in the size of the middle class.

Immigration of lower-class members may be again the cause of this phenomenon.

This is not the only criticism that could be levelled against Di Tella's hypothesis. The other major one is that, if one does not identify the famous turning point, the level of development corresponding to the minimum in the function of the size of the middle class, the hypothesis is not verifiable: it cannot be proven wrong. If, in fact, the size of the middle class decreases, we can state it has not yet reached the turning point; if it increases that it has already passed it. There is an answer for all possibilities.

This second criticism cannot be done away with in this analysis. Considerations should be made that I cannot sincerely imagine here, and that would, anyhow exceed the limits of this paper. The first, however, can be answered to, knowing the composition of the migrants to the regions we analyze: this can be done, with a degree of approximation, gathering information on the percentage of migrants to the region which earn less than 500 pesos (the minimum income) over the total labour force. Controlling for this percentage, we should be able to know the independent effects of

economic change. Stimulated by these doubts Urzúa ^{6/} repeated Di Tella's research with the same data as Di Tella's but referred to 1960. Parenthetically, these data - on Chilean regions - were produced by Mattelart and Garretón. ^{7/} He found that his data disapproved Di Tella's hypothesis of the curvilinearity of the relation between development and size of the middle class.

This is, in brief, the situation of the theory on regional development and size of the middle class. I will presently try these hypothesis out with my Mexican data. As I said, I will try to take into account the effects of differential immigration in the region, controlling the relation between development and stratification for the percentage of migrants over total population that earn less than 500 pesos. Of course, the present misery of the migrants does not imply necessarily that they were poor when they migrated, but I am afraid the assumption is unavoidable.

This is a simple analysis. There is material, however, for sophistication if sophistication is needed.

Table G gathers all relevant information for the preliminary test of the hypothesis. The scattergrams tabulating the size of the middle class with PRB (Producto Regional Bruto) per capita and with the percentage of PRB accounted for the industrial production, allows to make a few observations:

1. That there seems to be a relation between the PRB per capita and the size of the middle class; although, if we eliminate the extreme values of Distrito Federal, the relation is far less clear. It would be possible, but, I believe unnecessary, to compute some measure of the strength of the association.
2. That this relation is linear or, perhaps, curvilinear, but not, as Di Tella had found with Chile, with opposite directions within the set limits. This does not contradict Di Tella's hypothesis necessarily: it

^{7/} Armand Mattelart and M.A. Garretón, Integración nacional y marginalidad. Santiago de Chile, Editorial del Pacífico, 1965.

/could be

could be argued that all of Mexico's regions have already passed the level-limit of development beyond which the function changes sign. But then Di Tella's hypothesis cannot be invalidated.

3. That the relation between size of the middle class and industrialization (PI/PRB) is either non-existent, or weaker than the one found earlier.

4. That, as far as the data of Mexico indicate, selective migration does not affect the size of the middle class. We need to recall that it was thought selective migration could affect the size of the middle class, reducing or annulling the effect of economic change. If the relation between size of the middle class and economic growth is spurious, it should disappear within categories of the causal variable, in this case selective migration. To verify the validity of this, I have first listed the regions as to the proportion of their active population which is migrant and earns less than 500 pesos. Supposedly, this could measure the importance of the lower class migration into the region. Then, I have seen if, within one category of this variable (arbitrarily I have chosen the 4% as the dividing criterion), the relation between Regional Product per capita and size of the middle class held. Unexpectedly, although region differ substantially as to the percentage of their population which is constituted of poor migrants, there seems to be no relation between this percentage and size of the middle class, since the relation between Product per capita and size of the middle class does not appear smaller in our subsample than in the whole population of regions. This is because, apparently, the income distribution of migrants in the regions do not differ. It is a relatively interesting conclusion which would need further probing.

Appendix 1

In this appendix, there are gathered the most important tables that can be drawn from the second tabulation of the census samples of Mexico 1970. It needs to be recalled that the first set of tabulations already has been published in the CEPAL-UNICEF Programme of Tabulations.

These tables, however, do not cover all the wealth of information that exists in the tabulation, and that are available in the Social Development Division. The printouts, in fact, contain the following tables:

1. Economically active population by occupation, occupational category, industry, sex and area.
2. Economically active population by occupation, occupational category, sex, area and region.
3. Economically active population by occupation, occupational category, monthly income, region, sex, area and age.
4. Economically active population by occupation, occupational category, age and area.
5. Economically active population by age, sex, monthly income, region and area.
6. Economically active population by occupation, occupational category, income, education and area.
7. Economically active population by income, education, industry, age and area.
8. Economically active population by income, time of migration, region and age.
9. Active heads of household by occupation, occupational category, education, sex and area.
10. Population of ten year and more by income, activity, and education.
11. Population of ten years and more type of activity, income and region.
12. Population of six years and more by education, sex, age, region and area.
13. Population of six years and more by education, sex, age and region.
14. Females of 15 to 49 years by children age, education and area.

The tables that will be included in this appendix are the following:

MEXICO: OCCUPATIONAL STRATIFICATION, (concluded) 8

Appendix 2

I have anticipated in the text that the social stratification would substantially change according to our decision as to the criteria of division among classes. To see how much it would change, transforming these criteria, the stratification structures that could be obtained by two other conversion tables have been constructed. The conversion tables and the results are contained in the following tables. It needs only to add what is entirely obvious to the reader: that the changes are rather important: the lower class would be around 60% of the active population in one conversion table against 87% in another. The one I selected in the text seems to me more realistic than either of the two.

Appendix 2

Appendix 3

Since the information contained in the second tabulation of OMUECE 70 for the census sample of Mexico had at times too many categories, this rendering unreadable or difficult to understand the tables, it has been decided to join some categories into less but more meaningful ones: especially for what refers to the variables of income and region.

For what refers monthly to income, we joined the following brackets: 0-100, 101-200; 201-300, 301-500, into one bracket: 0-500. The reason for our operation, is that, we wanted to draw a line between the unemployed, underemployed or underpaid and the lowliest paid industrial workers. Now, the Mexican social legislation prescribes that the minimum salary in the region where the minimum salary is the minimum is 15,75 pesos daily (the maximum minimum salary is 46 pesos). Therefore, assuming the monthly working days to be thirty, the minimum monthly salary is 472 pesos, which, for lack of this limit in the census publication has been rounded to 500.

The other brackets have remained as in the census or, only when the cells would be too many, on account of the presence of many categories also in the variables income was crossed with, reduced to a more manageable number.

As to the second point, the regions, OMUECE takes into account, as is the census does, 32 administrative regions. Since, on one side, the information would be again difficult to manage, and, on the other, there are administrative regions that can be considered homogeneous among themselves, we have in some tables, presented the information not for all the regions, but only for a number of groups of them. For the operation of regionalization of Mexico, we have relied on Barkin and King (Desarrollo regional en México, México: Siglo XXI, 1971, pág. 61).

The authors joined the regions as follows:

/1. Peninsula

1. Península de Yucatan: Campeche, Quintana Roo and Yucatan.
2. Pacífico: Chiapas, Guerrero and Oaxaca.
3. Golfo: Tabasco and Veracruz.
4. Centro: Distrito Federal, Guanajuato, Hidalgo, México, Morelos, Puebla, Queretaro and Tlaxcala.
5. Occidente: Colima, Jalisco, and Michoacan.
6. Norte Central: Durango, Aguas Calientes, San Luis de Potosi, and Zacatecas.
7. Norte del Golfo: Nuevo León, and Tamaulipas.
8. Norte: Coahuila and Chihuahua.
9. Pacífico del Norte: Baja California Norte, Baja California Sur, Sonora, Sinaloa, and Nayarit.
